#### Abstract

The possibility of using instrumental neutron activation analysis to determine whether two bullet lead specimens have common or different sources has been examined. It has been found that the number of elements observable, and thus the number of points of comparison, is generally limited to three elements, due to dominance of antimony radioisotopes in the activated bullet lead specimens. This factor, coupled with a high degree of composition uniformity of bullet lead from at least one major manufacturer, imposes some limitations on the method. Thus, while differences in identification points definitively indicate a difference in sources, two bullets with the same patiern of only three identification points are not usually definitively identified as having a common source.

Recommendations are given with respect to extending the activation analysis technique to enable positive identification of bullet samples as being from common or different sources.

## SUMMARY

The possibility of utilizing instrumental neutron activation analysi: (NAA) for the comparison of bullet lead specimens has been investigated in two phases. In both phases bullet lead samples were activated by neutron bombardment at thermal neutron fluxes of $\sim 2 \times 10^{2} \mathrm{n} / \mathrm{cm}^{2}-\mathrm{sec}$ in a TRIGA Mark I nuclear reactor, and subsequently the induced gammaemitting radioisotopes were measured by multichannel gamma-ray spectrometry. Concentrations of antimony, an element often added to control bullet lead hardness, plus two other elements were usually determined by this procedure.

In the first phase of work experiments were carried out to see if the elements observed were of reasonably widespread concentration among a variety of bullets and to obtain an initial assessment of the uniformity of antimony concentration within a given bullet and with bullets from a common box of bullets. The findings were sufficiently encouraging to warrant a larger effort. Nost of the gamma-ray measurements in the early work utilized a $\mathrm{NaI}(\mathrm{Tl})$ detector. However, a 3 c.c. Ge(Li) detector showed that arsenic was a suitable candidate identification element even though the gamma ray of its indicator isotope, ${ }^{76}$ As ( $\gamma=0.559 \mathrm{MeV}$ ) is very near that of a longer-lived major antimony isotope, ${ }^{122} \mathrm{Sb}(\gamma=$ 0.564 MeV ).

The results of the first phase of work, taken in conjunction with a survey of the frequencies with which various calibers are involved in police work plus the constraints of time and funds, were used to define the kinds and numbers of samples to be taken and the analytical regime of a larger second phase effort.

The second phase effort utilized an experimental procedure similar to the preceding work, the chief exception being that a $35 \mathrm{c} . \mathrm{c} . \mathrm{Ge}(\mathrm{Li})$ detector was used in gamma-ray spectrometry measurements of activated samples. Altogether, 230 samples of bullet leads taken from 75 different lots of bullets that had been selected in conformity with the survey results were analyzed. The elements quantitatively determined in a majority of samples were antimony, copper, and arsenic.

It was found that the intra-lot uniformity of bullet leads with respect to the three elements was as good as the intra-box uniformity (i. e., the bullet lead within a box of bullets). The relative standard deviations regarding this uniformity were $\pm 4 \%$ for antimony, $\pm 23 \%$ for copper, and $\pm 44 \%$ for arsenic. Appropriately antimony is the most useful element for comparison purposes, and arsenic is the least useful.

Also, it was found that the copper and arsenic concentrations are correlated with antimony concentrations.

Most damaging to the forensic utility of purely instrumental NAA for bullet comparisons was the frequency with which antimony concentrations were observed to fall within the range of $0.7-0.8 \% \mathrm{w}$. This factor, coupled with the correlated concentrations of copper and arsenic and the larger variances of these two elements, contributed in large measure to the finding that less than half of the 75 lots of bullets were uniquely characterized by the concentrations of $\mathrm{Sb}, \mathrm{Cu}$, and As.

As a result of the foregoing it can be said that a significant difference in concentration of any one of the three elements between two bullet specimens indicates that they came from different lots, but that matching concentrations of all three elements does not indicate that two bullets come from the same lot.

Enhancement of the utility of the method to minimize the chance of accidental matching of two bullets from different lots is desirable.

This can be achieved either by (1) utilizing post-irradiation radiochemical separations to separate the dominant, interfering antimony radioisotopes, which would enable the measurement of more elements, or (2) by incorporating a unique combination trace element tag, which could be easily measured by NAA, in each lot of bullets.

## 1. INTRODUCTION

The identification of bullets is of major interest in criminalistics. The primary technique applied to this end has been the examination of striations imposed on the bullet by the gun during firing. A bullet in evidence will be compared with one fired from a weapon that is linked to a suspect. If the two bullets have matching striations, then the evidence bullet may be considered as linked to the suspect. Unfortunately, a bullet fired in the field often undergoes such severe encounters that the markings are obliterated for all practical purposes. Sometimes the bullet is even fragmented. With the possibility in mind that instrumental NAA (Neutron Activation Analysis) might provide a means of definitively comparing spent bullet with unfired bullets in a suspect's weapon, which would be particularly useful where markings on the spent bullet (or fragment) were absent, the study described therein was initiated.

The possibility that other potential uses for the NAA characterization of bullets could exist augmented the initial consideration. For example, in cases where the weapon involved in a shooting incident could not be found, it could be of interest to compare an evidence bullet with unfired bullets found in the possession of a suspect. Or, as a corollary, in cases where a multiplicity of weapons were fired it would be of interest to compare certain spent bullets with unfired bullets found in selected weapons.

## 2. EXPERIMENTS AND RESULTS

The examination of bullets by NAA involved the exposure of weighed bullet lead samples to neutron bombardment in the Gulf General Atomic TRIGA Mark I nuclear reactor for purposes of generating radioactive analytical indicator radioisotopes from the elemental constituents of the samples. In some experiments the irradiation was carried out for $\therefore 1$ minute at a thermal neutron flux of $2.8 \times 10^{12} \mathrm{n} / \mathrm{cm}^{2}-\mathrm{sec}$, and the ir radiated samples were examined by multichannel gamma-ray spectrometry within a few minutes after termination of the irradiation. In other experiments irradiations were carried out for 30 minutes at a thermal neutron flux of $1.8 \times 10^{12} \mathrm{n} / \mathrm{cm}^{2}-\mathrm{sec}$, and the irradiated samples were counted at longer decay times.

Examination of irradiated specimens by counting was carried out with 3-in. x 3-in. $\mathrm{NaI}(\mathrm{Tl})$ detectors coupled to multichannel pulse height analyzers, particularly in the early phases of the work. ${ }^{(1)}$ Later, Ge(Li) detectors were used so that indicator radioisotopes giving rise to gamma rays of similar energy could be distinguished and quantitated.

In initial experiments tabulated photopeak yield values (in photopeak counts per minute per gram of element) were used to obtain elemental yield values from the quantitized photopeaks.

Once it became clear which elemental constituents of bullet lead were of most interest in this study, weighed comparator standards of these elements were irradiated and measured with, and in identical manner to, the samples. Thus, concentrations of key elements in the samples were derived by comparison of appropriate, quantitized photopeaks in the sample and comparator spectra.

Clean polyethylene vials were used to contain the samples and standards during irradiation and counting. Usually the samples, which were solid pieces, were transferred to unirradiated vials for counting in order to dispel ${ }^{41} \mathrm{Ar}$ and avoid vial blanks.

## 2. 1 INITIAL EXPERIMENTS AND RESULTS

Small samples (10-100 mg slices) of bullet leads from a variety of bullets were irradiated for 15 seconds, and counted for one minute ( $\mathrm{NaI}(\mathrm{Tl})$ detector) beginning at one minute after the end of the irradiation. A number of elements were quantitatively determined from the intensities of observed photopeaks, and the results are given in Table 1.

Lead samples from a few of the foregoing bullets were examined by emission spectroscopy in order to ascertain the degree to which this method and NAA complement one another. The emission spectroscopy results are given in Table 2.

The initial gamma-ray spectra of irradiated, antimony-containing lead sample were fairly complex in the $0.50-0.70 \mathrm{MeV}$ region, which rendered the determination of silver by means of the 24 second isotope, ${ }^{110} \mathrm{Ag}\left(\mathrm{E}_{\mathrm{Y}}=0.658 \mathrm{MeV}\right)$, somewhat difficult. This is illustrated in Fig. 1.

It was ascertained that the complexity in the $0.50-0.70 \mathrm{MeV}$ region was due to the production of a short-lived antimony isotope by irradiating a 1.2 mg portion of antimony metal for 15 seconds at a thermal neutron flux of $2.8 \times 10^{12} \mathrm{n} / \mathrm{cm}^{2}-\mathrm{sec}$ and measuring its gamma-ray spectra starting at 0.5 minutes and 4.75 minutes after the irradiation. The initial spectrum, shown in Fig. 2, has 0.51 MeV and " 0.62 " MeV peaks similar to those in Fig. 1. The later spectrum (in Fig. 2) shows that the responsible isotope is short-lived; the 0.564 MeV photopeak of 2.8 day ${ }^{122} \mathrm{Sb}$ is visible in the later spectrum.

The short-lived radioisotopes generated from antimony by neutron activation include 3.5 minute ${ }^{122 \mathrm{~m}} \mathrm{Sb}$, which has gamma rays of 0.061

Fig. 2. Gamma-ray spectrum of activated $\mathrm{Sb}(1.2 \mathrm{mg})$
$\operatorname{MeV}(50 \%$ yield) and 0.075 MeV ( $17 \%$ yield). The weak gamma rays of 122 m Sb are shown as a composite peak in both Figs. 1 and 2. The irradiation of ${ }^{121} \mathrm{Sb}$ ( $99 \%$ enriched, obtained from Oak Ridge National Lab) produced ${ }^{122 \mathrm{~m}} \mathrm{Sb}$, as shown by the spectra in Fig. 3. The composite 0.061 MeV-0.075 MeV peak is clearly seen, and the 0.564 MeV photopeak from 2.8 day ${ }^{122} \mathrm{Sb}$ is in evidence, also.

Another short-lived isotope is 1.3 minute ${ }^{124 \mathrm{~m}} \mathrm{Sb}$, which emits gamma rays of 0.505 MeV ( $20 \%$ yield), 0.603 MeV ( $20 \%$ yield), and 0.644 MeV ( $20 \%$ yield). Spectra of this isotope were obtained subsequent to the irradiation of ${ }^{123} \mathrm{Sb}$ ( $99 \%$ enriched, from ORNL) as shown in Fig. 4. The 0.505 MeV peak and the composite 0.603 MeV plus 0.644 MeV peak which are clearly shown in Fig. 4, show that the ${ }^{124 m^{m}}$ Sb is responsible for the complexity of the $0.5-0.7 \mathrm{MeV}$ region of Fig. 1.

The data obtained from the measurements of irradiated, enriched ${ }^{121} \mathrm{Sb}$ and ${ }^{123} \mathrm{Sb}$ indicated the photopeak intensities of the short-lived antimony isotopes shown in Table 3.

Elucidation of the $0.50-0.70 \mathrm{MeV}$ region of spectra from activated antimony has made it possible to avoid excessive errors in the computation of silver concentrations when a strong 0.66 MeV peak, due to 24 second ${ }^{110} \mathrm{Ag}$, is observed. The 0.66 MeV peak in Fig. 1 is evidence of the presence of ${ }^{110} \mathrm{Ag}$ activity; but it is a fairly weak peak - therefore, a silver concentration was not computed in this case. In general, the Ag concentration could be determined with a precision of $\pm 50 \%$ relative.

An examination of 18 bullets obtained from the Bureau of Criminal Identification and Investigation (CII) laboratory of the California State Department of Justice was carried out. All bullets were 0.38-caliber (either Smith and Wesson or Colt New Police), but no two bullets were alike with respect to all of the following: manufacturer, $S \& W$ variant, Colt N. P. variant, case, jacket, and lot. These bullets were examined

initially with respect to antimony concentration to further study the variation of this element in bullets known to be different from one another. However, at a later time the silver and arsenic contents were examined. A Ge(Li) detector ( $3 \mathrm{c} . \mathrm{c}$.) was used for the measurement of arsenic (to be discussed later). A summary of the findings is given in Table 4.

## 2. 2 BULLET UNIFORMITY EXPERIMENTS

From the foregoing experiments it seemed possible that instrumental activation analysis can differentiate between bullets that are not from the same batch of lead. However, it was necessary to examine bullets from a given batch of lead, and even individual bullets, for uniformity of composition - especially with respect to antimony concentration - in order to ascertain that compositional differences are not due to batch inhomogeneity.

### 2.2.1 Bullet Lead Homogeneity

A rod of bullet lead, which contained a nominal $1-1 / 2 \% \mathrm{w} \mathrm{Sb}$, was sampled from the exterior to the interior. Two groups of samples were obtained - a group of eight samples weighing from 62.3 to 113.2 mg each and a group of 12 weighing from 7.20 to 27.60 mg each. The samples were activated for 30 minutes, allowed to decay for eight hours, and measured by a multichannel gamma-ray spectrometer (using a 3-in. x 3-in. $\mathrm{NaI}(\mathrm{Tl})$ detector). The net ${ }^{122} \mathrm{Sb}$ photopeak ( 0.564 MeV ) cpm per milligram of each sample is given in Table 5. The average of the first eight samples is $5450 \mathrm{cpm} / \mathrm{mg}$ with a standard deviation of $3.85 \%$ of the value. The average of samples 9 through 20 is $5505 \mathrm{cpm} / \mathrm{mg}$ with a standard deviation of $2.50 \%$ of the value. The average of all 20 samples is $5483 \mathrm{cpm} / \mathrm{mg}$ with a standard deviation of $\pm 3.00 \%$ of the value.

In a second test of bullet uniformity, a Remington 0.38 -caliber bullet was sampled from the side to the center and processed in the same

manner as the Norma bullet lead. The results are given in Table 6. The average net counts per minute in the ${ }^{122} \mathrm{Sb}$ peak per milligram of lead was $1123.3 \mathrm{cpm} / \mathrm{mg}$, and the standard deviation was $2.85 \%$ of the value.

### 2.2.2 Bullet-to-Bullet Similarity

A multiplicity of bullets from each of a number of boxes of bullets were sampled. The coating (grease, copper, and/or bronze) was removed from each bullet with organic solvent and weak nitric acid, and bullets were washed with water and dried before sampling. Again the emphasis was placed on the examination of antimony concentration; how ever, two brands of 0.22 -caliber bullets that had similar antimony concentrations were examined for trace elements. Results are given in

## Table 7.

### 2.2.3 Initial Experiments with a Ge(Li) Detector

A $3 \mathrm{c} . \mathrm{c}$. $\mathrm{Ge}(\mathrm{Li})$ detector was found to be able to measure As in the presence of Sb , provided the $\mathrm{Sb} / \mathrm{As}$ ratio was not too great. The radioisotopic analytical indicator for As is 26.5 hour ${ }^{76}$ As, which emits a 0.559 MeV gamma ray. Thus only 0.005 MeV separates the energy of the ${ }^{76}$ As gamma ray from that of 2.8 day ${ }^{122} \mathrm{Sb}\left(\mathrm{E}_{\mathrm{Y}}=0.564 \mathrm{MeV}\right)$. Never theless, the $G e(L i)$ detector was capable of resolving the two gamma rays, as shown in Fig. 5. This figure shows the gamma-ray spectrum obtained from a 99.6 mg portion of lead from a 0.22 caliber bullet (Sears) that had been irradiated for 30 minutes and counted for 10 minutes (at two hours after the irradiation) with the $3 \mathrm{c} . \mathrm{c}$. $\mathrm{Ge}(\mathrm{Li})$ detector. Examination of five bullets from the same box (Sears, 0.22 -caliber) showed that the arsenic content was $285 \pm 40 \mathrm{ppm}$. A Peters 0.22 -caliber bullet had 345 ppm As, a Western 0.22 -caliber bullet had 78 ppm As, an Imperial 0.22 caliber bullet had $<4 \mathrm{ppm}$ As, and a Lapua 0.22 -caliber bullet had $<5$ ppm As.

### 2.3 FINAL EXPERIMENTS AND RESULTS

Based upon the results of the initial experiments described in the preceding section, it was estimated that 30 different bullets from each of the six major calibers of cartridge ( $0.22,0.25,0.30,0.32,0.38$, and 0.45 ) should be analyzed in order to properly characterize the population of bullet leads. ${ }^{(1)}$ However, the constraints of time and effort, taken in context with other considerations, prevented the full realization of this task.

The other considerations included the fact that the 3 c . c. Ge(Li) detector had since been replaced with a superior 35 c . c. Ge(Li) detector, and it was desired that all further work be done with the better detector. Thus, the previous work, which had not been done with this equipment, could not be deemed to carry a full measure of contribution tow ard fulfillment of the goal.

Another factor was that it could not be considered sufficient to analyze simply one bullet from each different kind (as specified by manufacturer, lot number, and box). It was necessary to obtain further bullet uniformity data, including intra-box, inter-box (intra-lot, and inter-lot comparisons.

In consequence of the above needs, the work of the original plan, which called for the analysis of 180 different bullets in total, would have escalated considerably beyond reasonable limits. Therefore, advantage was taken of information obtained from California criminalists regarding the frequency with which various calibers of handguns are brought to their attention.
(2) These frequencies were as follows:

$$
\begin{aligned}
& 0.22 \text { caliber }-32 \% \\

$$

Clearly, then some stratification in sampling was called for rather than sampling all calibers equally. Also, discussions with gun dealers, policemen, and criminalists suggested that 0.357 magnum bullets, shotgun slugs, and 00 buckshot should be sampled.

Accordingly 242 samples were acquired and analyzed much as in previous experiments, except that the $35 \mathrm{c} . \mathrm{c}$. Ge(Li) detector, coupled to a 4096 channel pulse height analyzer, was used for gamma-ray spectrometric measurements. Unfortunately, the timing cycles in these experiments precluded the observation of silver. A number of the bullets had copper jackets, and it was found subsequent to irradiation that microscopic specks of copper remained on a few samples. This happenstance, plus a few malfunctions of the pulse height analyzer necessitated deletion of 12 samples. The remaining 230 samples were distributed as follows:
0.22 caliber - 70 bullets among 21 different lots
0.25 caliber - 5 bullets among 1 lot
0.32 caliber - 23 bullets among 10 different lots
0.357 caliber - 19 bullets among 3 different lots
0.38 caliber - 72 bullets among 26 different lots

9 mm caliber - 15 bullets among 3 different lots
0.44 caliber - 11 bullets among 3 different lots
0.45 caliber - 6 bullets among 3 different lots

12 gauge - 9 projectiles among 5 different lots
The initial 242 bullets among 75 different lots are itemized in Table 8. wherein it may be seen that several variants among the major calibers were sampled, e. g., 0.38 automatic, 0.38 CNP (Colt New Police), 0.38 S\&W (Smith \& Wesson), and 0.38 Special.

The previously mentioned problem with microscopic specks of copper was most frequent among the first samples analyzed, and it

occurred even among some specimens of bullets not initially coated with copper. Presumably the copper-colored, shiny particles were brass from the cartridge case in some instances. After the problem was recognized, samples were examined under the microscope prior to irradiation.

The results obtained by NAA of the samples are given in Table 9. It should be mentioned that no attempt was made to reirradiate specimens subsequent to any analytical difficulty due to the lifetime of radioactive species present and time constraints.

## 3. DISCUSSION

### 3.1 INITIAL EXPERIMENTS

Antimony concentrations, which were the chief focus of the work, have been seen to be very uniform within a single bullet (Tables 5 and 6) and within bullets from the same box of bullets, excepting perhaps the Peters 0. 22-caliber bullets (Table 7). The usual standard deviation of the antimony concentration within either a single bullet or within a box of bullets is about $\pm 3 \%$ of the concentration value. It is worthy of note, from Tables 5 and 6, that, because of the thickness uniformity of bullet slices, the antimony-122 photopeak specific activity was essentially independent of sample weight over a wide range of sample weights.

Among the bullets listed in Tables 1, 4, and 7 a majority have a distinctive antimony concentration. However, in some cases there is an overlap of values within the usual $\pm 3 \%$ relative standard deviation: (1) a Remington-Peters 0.38 -caliber bullet and a Remington 0.38 -caliber bullet were found to contain $0.85 \%$ and $0.87 \%$ w antimony, respectively; (2) the Peters and Remington 0.22-caliber bullets were found to contain $0.87 \%$ and $0.85 \%$ w antimony, respectively; (3) the Lapua and Sears 0.22-caliber bullets contained $1.22 \%$ and $1.26 \% \mathrm{w}$ antimony, respectively; (4) a U.S. Cartridge Co. and a Winchester 0.38-caliber bullet each contained $1.55 \%$ w antimony, and (5) a Peters and a Western 0.38-caliber bullet each contained very close to $3.00 \% \mathrm{w}$ antimony. In cases (3), (4), and (5), however, the bullets could be distinguished from one another on the basis of trace-element constituents, while in cases (1) and (2) sufficient traceelement information was not gathered to determine if the pairs could be distinguished.

Those bullets for which upper limits of antimony concentration are reported can all be distinguished on the basis of trace-element information.

While it could be said from these results that bullets with different antimony concentrations have different origins, the data indicated that there was some chance that whole bullets with the same antimony level may have a different origin, and that there was some lesser chance that whole bullets with the same antimony and trace-element levels may have a different origin.

If the caliber of bullet cannot be determined, as when the sample consists of a bullet fragment, the foregoing overlapping cases number (1) and number (2) become a group of four indistinguishable bullets on the basis of antimony level, and in the absence of sufficient trace-element data. Similarly, a 0.30 =caliber Remington rifle bullet and a 0.38 -caliber Winchester bullet join the two bullets of overlapping case number (3), although the available trace-element information makes it possible to dis tinguish between the bullets in this group. Also, a 0.38 -caliber Winchester bullet with $3.09 \% \mathrm{w}$ antimony and a 0.30 -caliber Sierra bullet with $3.10 \% \mathrm{w}$ antimony overlap with respect to antimony, but can be distinguished by virtue of the large tin concentration in the latter.

The initial work established a basis upon which to judge a lack of commonality between bullets or bullet fragments with different antimony levels; and the consistency of antimony concentration found in single bullets and among bullets of common log origin is seen an important factor in establishing commonality between bullets or bullet fragments.

### 3.2 FINAL EXPERIMENTS

These experiments allowed the further examination of intra-box bullet uniformity, as shown in Table 10. Except that large variances are

[^1]associated with very low antimony concentrations, the magnitudes of the concentration variances are not well correlated with the concentration values. Thus, it is somewhat meaningful to note that the average standard. deviations for $\mathrm{Sb}, \mathrm{Cu}$, and As are $\pm 0.036 \% \mathrm{w}, \pm 74 \mathrm{ppm}$, and $\pm 45 \mathrm{ppm}$, respectively.

Also, the series of experiments permitted comparison of bullets from common lots but different boxes, as shown in Table 11. The average standard deviations for the elements in this context are $\mathrm{Sb}- \pm 0.031 \% \mathrm{w}$, $\mathrm{Cu}- \pm 67 \mathrm{ppm}$, and As $- \pm 38 \mathrm{ppm}$. The fact that these averages are somewhat better than those cited in the foregoing paragraph (a result of larger numbers of individual samples represented in each value) indicates that the degree of uniformity of bullets within a box extends to the multiplicity of boxes from the same lot of bullets.

The mean values for antimony, copper and arsenic for each of the 75 different lots of bullets are given in Table 12. Where the lot is represented by a single sample, or value only, no standard deviation is given. It can be seen that, except for the 12 gauge, 2-3/4-in., rifled slugs, there are no significant differences with respect to concentration ranges or distributions of the elements between the various calibers. It is clear that it is not possible to determine the caliber of a projectile from the concentrations of the elements in question. On the other hand, the total set of 75 lots may be utilized in obtaining generalized statistics for all calibers.

The exploration of generalized statistics is facilitated by the ordering of results given in Table 12 with respect to the element of greatest intra-lot uniformity, antimony. This is done in Table 13.

An initial inspection of Table 13 reveals that $\sim 10 \%$ of the samples have low impurity concentrations ( $\sim \leq 0.1 \%$ ) of antimony, while the rest have antimony levels usually associated with deliberate antimony additions

to achieve desired physical properties (chiefly hardness). Also, the dominance of Remington ammunition in the middle ranks of Table 13 is obvious.

The 75 lots included 39 lots of Remington bullets (including one lot from the parent company, Olin-Mathieson, and a number of lots from the subsidiary company, Peters), 28 lots of Winchester-Western bullets, four lots of Speer bullets, and four lots of Federal Cartridge Co. bullets. It is instructive to note the following distribution of brands within consecutive ranks of 25 :

| Order <br> No. | Numbers of Lots |  |  |  |
| :---: | :---: | :---: | :---: | :---: |
| $1-25$ | $\frac{\text { Rem. }}{7}$ | $\frac{W-W}{15}$ | $\frac{\text { Fed. }}{1}$ | $\frac{\text { Speer }}{2}$ |
| $26-50$ | 21 | 3 | 1 | 2 |
| $\frac{51-75}{\text { All }}$ | $\underline{11}$ | $\frac{10}{29}$ | 28 | $\frac{2}{4}$ |

The average relative standard deviations for the three elements in question are antimony $- \pm 4 \%$ of the value (leaving out the lots with $<0.1 \% \mathrm{w} \mathrm{Sb}$, which have quite large $\sigma^{\prime} \mathrm{s}$ ), copper $- \pm 23 \%$ of the value, and arsenic $- \pm 44 \%$ of the value. Thus, antimony might be expected to be more definitive than the other two elements for comparison purposes. This is true at relatively low and high Sb concentrations, but (again referring to Table 13) not for the many lots of Remington bullets of middle ranks.

For example, let us say that an antimony value is distinct if it is $0.75 \% \mathrm{w}$ and a comparison sample is not within $3 \sigma( \pm 0.09 \% \mathrm{w})$ of that value. If the 75 lots studied are representative of the population of bullets, then the fact that 25 of the lots have antimony values falling within that range indicates a large chance that, at this level, different bullets
will not be distinguished on the basis of Sb concentrations alone. If we relax the criterion to a range of $\pm 2 \sigma$ (i.e., distinct if another bullet is not within $0.69-0.31 \% \mathrm{w} \mathrm{Sb}$, we do not find much improvement -23 lots of the 75 have Sb concentrations within that range.

The examination now turns to the question of aid from copper and arsenic in the midde ranks of bullets. Assume that a bullet in question has the following concentrations (with average standard deviations): $0.75 \pm 0.03 \% \mathrm{w} \mathrm{Sb}, 400 \pm 92 \mathrm{ppm} \mathrm{Cu}$, and $100 \pm 44 \mathrm{ppm}$ As. Assume $2 \sigma$ to define the distinctive range in each case. Then the ranges of interest are:

$$
\begin{aligned}
& \mathrm{Sb}: \quad 0.69-0.81 \% \text { w Sb } \\
& \mathrm{Cu}: \quad 216-584 \mathrm{ppm} \mathrm{Cu} \\
& \mathrm{As}: \\
& 12-188 \mathrm{ppm} \mathrm{~A}
\end{aligned}
$$

Among the 75 lots of bullets the following fall within the three simultaneous ranges of interest: W24A2B (rank 26), J09P (rank 27), unk (samples 91-105, rank 29), J12P2D (rank 35), M11E-20P (rank 41, H09HG23LD (rank 42), 3 TF27E165 (rank 44), and H09HH05SD (rank 45) - over $10 \%$ of the 75 lots.

Exact statistical definition of the degree to which bullets may be distinguished from one another is rendered difficult because the three elements do not have Gaussian concentration distributions among the population sample (neither normal nor log-normal). Rather, the antimony concentrations are unnaturally distributed as a result of deliberate additions at selected levels of concentration; and the other two elements have unnatural distributions that are probably associated with antimony. Correlation of concentration ranking orders between antimony and copper, and between antimony and arsenic substantiate this latter assertion. These correlation coefficients, $R$, are as follows:

$$
\begin{aligned}
& \mathrm{Sb}: \quad \mathrm{Cu}-\mathrm{R}=0.38 \\
& \mathrm{Sb}: \mathrm{As}-\mathrm{R}=0.55 .
\end{aligned}
$$

Both values indicate significant correlations among the set of 75 lots. Thus the number (8) of indistinguishable bullet lots in the example of the preceding paragraph is not surprising.

Examination of Table 13 shows that 12 of the first 25 ranks, 2 of the second 25 ranks, and 18 of the last 25 ranks are uniquely identified by the three elements. While the second 25 ranks are highly biased by the similarity among the 21 Remington members of the group, the distinctiveness among the other two groups of 25 samples is not great.

The earlier experiments, which addressed 30 different lots of handgun ammunition, involved a smaller proportion of Remington and Winchester bullets, and the antimony values of the 30 lots of bullets were much more distinctive than in the case of the later experiments. However, if one examines the six Remington, Remington-Peters, and Peters results of the earlier studies, it is found that they anticipate in miniature the later results ( Sb values were $0.92,0.87,0.87,0.85,1.94$, and $2.99 \%$ ).

The preponderance of Remington and Winchester ammunition taken for the later study is consistent with the dominant market position of these companies. While a more ideal correspondence between the sample selection and an individual manufacturer's share of the market might have been achieved, the over-all results would have been substantially the same: i. e., Remington's bullet uniformity and strong market position lend a marked negative aspect to the probability of distinguishing between two bullets by purely instrumental NAA.

It is doubtful that the measurement of silver would have served to effect a unique determination among each of the 75 lots of bullets. While the earlier investigation solved the major difficulties in observing silver,
the analyzed precision finally achieved was still comparatively poor, and the obvious uniformity of bullets from a major supplier would undoubtedly extend to this element also. Note, for example, the similarity of Ag values ( 3.6 ppm and 3.1 ppm ) in the Remington-Peters $S \& W$ and C. N. P. bullets of Table 4.

Concurrent work with other evidence materials, such as paper ${ }^{(3)}$ and paint, ${ }^{(4)}$ has shown with significant confidence that accidental matching of different samples has not occurred and usually requires the measurement of $z 5$ elements. Had this information been available sooner, the attack on the subject of bullet identification would have been quite different in the final study, since the earlier study showed that instrumental NAA did not usually observe this many elements in bullet lead. Rather, post-ir radiation radiochemical separations would have been used to improve the possibility of observing a larger number of elements.

Although the present work has not provided a fully adequate means of comparing bullet specimens, as had been hoped, it has defined the scope of work necessary to achieve the desired goal.

Based upon the present findings two alternative approaches to the task are attractive. One approach would follow the course of postirradiation radiochemical separations to discern and quantitate at least six elements in bullet lead. This possibility is highly feasible, since removal of interference from the dominant antimony radioisotopes would open the specimens to the full sensitivity of the very powerful NAA technique. The larger number of observed elements, each of which would serve as an identification point, would greatly improve the reliability with which different bullets could be distinguished. As a result, the matching of two specimens from a common source would have much greater credibility. The use of radiochemistry would be precluded only where the specimen was small and required as an exhibit.

The alternative approach would involve the distinctive tagging of bullet leads with combinations of elements, in small amounts, that would be easily observed by instrumental NAA. Preliminary discussions with cartridge manufacturers indicate that this would be difficult to implement in a practical way. Nevertheless, if the importance of the task warranted the necessary alterations in manufacturing procedures, the tagging approach could be realized. With three appropriate tagging elements, each selected to have a certain individual concentration within potential concentration ranges covering three orders of magnitude, at least onemillion distinctive tagging codes could be devised. Clearly, within any reasonable time scale of interest, all lots of bullets manufactured in the United States could have a unique tag.

Altogether the present study has provided essential information concerning the problem in question, and may be considered as a milestone in the progression toward a complete solution of the problem. The demonstrated intra-lot uniformity is an essential factor in the comparison of bullet leads via their elemental constituents, and it has been defined that $\geq 6$ elements should be measured to achieve definitive comparisons via measurement of intrinsic constituents.

## 4. CONCLUSIONS

The number of identification points developed by instrumental NAA is too limited to provide a means of always discerning between bullets from different lots. Wherever, two bullet specimens have concentrations of antimony and/or other measured elements (e.g., copper, arsenic) that are different, after allowing for intra-lot variations defined in this work, it is safe to conclude that the two specimens come from different lots. However, if the concentrations of $\mathrm{Sb}, \mathrm{Cu}$, and As are the same (again allowing for intra-lot variations), it is not safe to say that the bullets come from the same lot. Improvement of this situation requires an extended program to either (1) expand, with radiochemical techniques, the number of observed elements, or (2) implement a program of tagging bullets with unique concentration codes of added trace elements that are easily measured by instrumental NAA.

[^0]:    ${ }^{a}$ The plus-or-minus values represent one standard deviation determined from counting statistics only.

[^1]:    ${ }^{\text {a }}$ Based on variation between samples. When unly une result is available, this is indicated by (s. v.), and no standard deviation is given.

[^2]:    ${ }^{a}$ One value rejected on the basis of Chauvenet's Criterion.
